INTRODUCTION AND PROCEDURES

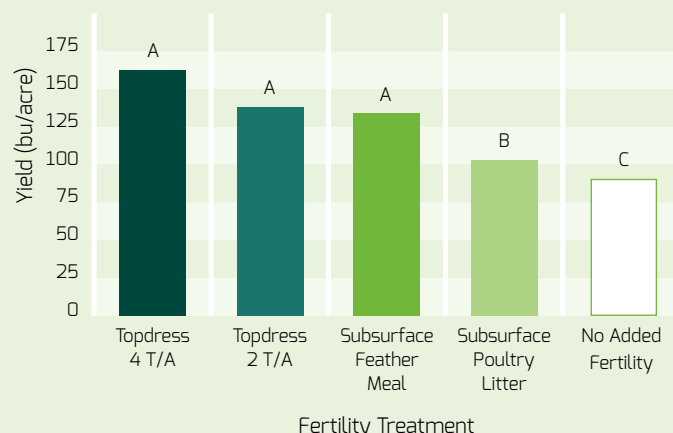

In the fall of year 1 of the study, Rodale Institute, in collaboration with USDA-ARS Beltsville Agricultural Research Center and North Carolina State University, were awarded a USDA BRCs Conservation Innovation Grant to demonstrate the integration of starter fertilizers (pelletted manure) and their impacts on yield and weed competition in cover crop-based, reduced-tillage organic corn production. The aim of this article is to present readers with findings from demonstration trials conducted at various locations for two years and conclude with recommendations based on information gained from this project.

TEST RESULTS

Field plots at Beltsville year 1, Kinston, year 2, and Salisbury year 1 and year 2 all had excellent weed suppression and corn yield was similar between the high and low rate broadcast litter treatments ranging between 145 to 165 bu/acre (Fig. 1). However, corn yield was reduced

with the subsurface poultry litter and no added fertility treatments to ~100 bu/acre. Feather meal subsurface banding yielded 30% more than in the subsurface poultry litter treatment.

Figure 1: Corn yield averaged over Beltsville Year 1, Kinston Year 2, Salisbury Year 3, and Salisbury Year 4.

8000 # PL	4000 # PL	515 # (13-0-0)	465 # PL
240 Units of N	120 Units of N	67 Units of N	14 Units of N
\$50/ton	\$100/ton	\$800/ton	
\$200/acre	\$200/acre	\$200/acre	

CONCLUSION

At Kinston in Year 1, high levels of weed competition were observed and corn grain yields were reduced with subsurface banded lower fertility treatments. However, at the high rate topdress PL treatment corn biomass (Photo) and corn grain yield were greatest, where corn proved competitive with the weeds.
